Lecture 11

based on lectures by Jean-Christophe Filliâtre and Léon Gondelman previous editions by João Costa Seco, Luís Caires, and Bernardo Toninho

Today: Optimizing Compiler, part 1

- 1. instruction selection
- 2. RTL (Register Transfer Language)
- 3. ERTL (Explicit Register Transfer Language)
- 4. LTL (Location Transfer Language)

Goal for the next two lectures: writing an optimizing compiler.

We intend to use x86-64 in the best possible way, notably

- its 16 registers
 - to pass parameters and to return results
 - for intermediate computations
- its instructions
 - such as the ability to add a constant to a register

add \$3, %rdi

Emitting optimized code in a single pass is doomed to failure.

We decompose code production into several phases:

- 1. instruction selection
- 2. RTL (Register Transfer Language)
- 3. ERTL (Explicit Register Transfer Language)
- 4. LTL (Location Transfer Language)
- 5. linearization

(We follow the architecture of the CompCert compiler by Xavier Leroy; see http://compcert.inria.fr/).

Compiler Phases = Many ASTs

The starting point the abstract syntax tree output by the type checker.

This compiler architecture is independent of the programming paradigm (imperative, functional, object oriented, etc.).

It is illustrated on a small fragment of C.

A small fragment of C with

- integers (type int)
- heap-allocated structures, only pointers to structures, no pointer arithmetic
- functions
- library functions putchar and malloc

To keep it simple, we assume 64-bit signed integers for values of type int (unusual, but standard compliant) so that integers and pointers have the same size.

```
\mid if (E) S else S
         | E op E | - E | ! E
                                                                        \mid while (E) S
         | x(E,...,E)
                                                                           return E;
              sizeof(struct x)
                                                                B \rightarrow \{V...VS...S\}
 \begin{array}{ccc} L & \rightarrow & x \\ & | & E \rightarrow x \end{array}
                                                                V \rightarrow \text{int } x, \dots, x;
op \rightarrow == | != | < | <= | > | >= | && | | | + | - | * | /
                                                                        | struct x *x, ..., *x;
                                                                T \rightarrow \text{int} \mid \text{struct } x *
 D \rightarrow T \times (T \times, ..., T \times) B
| \text{ struct } \times \{V ... V\};
                                                                P \rightarrow D...D
```

```
int fact(int x) {
  if (x <= 1) return 1;
  return x * fact(x-1);
}</pre>
```

```
struct list { int val; struct list *next; };
int print(struct list *1) {
  while (1) {
    putchar(1->val);
    1 = 1->next;
  }
  return 0;
}
```

Starting Point

We assume that type checking is done.

In particular, we know the type of any sub-expression.

Note: for mini-C, types are not useful for code generation; yet,

- type checking ensures some form of safety e.g. we do not confuse an integer and a pointer
- for a larger fragment of C, types would be needed e.g. to select signed vs unsigned operations, to perform pointer arithmetic, etc.

Phase 1: Instruction Selection

11

The first phase is instruction selection.

Goal:

- replace C arithmetic operations with x86-64 operations
- replace structure field access with explicit memory access

Arithmetic Operations

Naively, we can simply translate each C arithmetic operation with the corresponding x86-64 operation.

However, $\times 86-64$ provides us with better instructions in some cases, notably

- addition of a register and a constant
- bit shifting to the left or to the right, corresponding to a multiplication or a division by a power of 2
- comparison of a register and a constant

Besides, it is advisable to perform as much evaluation as possible during compilation (partial evaluation).

Examples: in some cases, we can simplify

- $(1+e_1)+(2+e_2)$ into e_1+e_2+3
- e+1 < 10 into e < 9
- $!(e_1 < e_2)$ into $e_1 \ge e_2$
- 0 × *e* into 0

Crucial: the semantics must be preserved!

If some left/right evaluation order would be specified, we could simplify $(0-e_1)+e_2$ into e_2-e_1 only when e_1 and e_2 do not interfere.

For instance if e_1 and e_2 are pure, i.e., without side effect.

With C , the evaluation order is not specified, so we can make the simplification.

With unsigned C arithmetic, we could not replace e+1 < 10 with e < 9 since e+1 may be 0 by arithmetic overflow (the standard says that unsigned arithmetic wraps around).

If e is the greatest integer, e+1 < 10 holds but e < 9 does not.

With signed arithmetic, however, arithmetic overflow is an undefined behavior (meaning that the compiler may choose any behavior).

Consequently, we can turn e+1<10 into e<9 with type int.

We can replace $0 \times e$ with 0 only if expression e has no side effect.

Since our expressions may involve function calls, checking whether *e* has no effect is not decidable.

But we can over-approximate the absence of effect:

```
pure(n) = true
pure(x) = true
pure(e_1 + e_2) = pure(e_1) \land pure(e_2)
\vdots
pure(e_1 = e_2) = false
pure(f(e_1, ..., e_n)) = false (we don't know)
```

To implement partial evaluation, we can use smart constructors.

A smart constructor behaves like a syntax tree constructor but it performs some simplifications on the fly.

Example: for addition, we introduce a smart constructor such as

```
val mk_add: expr -> expr -> expr (* OCaml *)
```

Expr mkAdd(Expr e1, Expr e2) // Java

Some possible simplifications for addition:

```
\begin{array}{rcl} \operatorname{mkAdd}(n_1,n_2) &=& n_1+n_2 \\ &\operatorname{mkAdd}(0,e) &=& e \\ &\operatorname{mkAdd}(e,0) &=& e \\ \operatorname{mkAdd}(\operatorname{addi}\ n_1\ e,n_2) &=& \operatorname{mkAdd}(n_1+n_2,e) \\ &\operatorname{mkAdd}(n,e) &=& \operatorname{addi}\ n\ e \\ &\operatorname{mkAdd}(e,n) &=& \operatorname{addi}\ n\ e \\ &\operatorname{mkAdd}(e_1,e_2) &=& \operatorname{add}\ e_1\ e_2 & \operatorname{otherwise} \end{array}
```

Remark: instruction selection is where we can make a good use of lea.

Instruction selection is thus a recursive process over the expressions:

$$\begin{array}{lcl} \mathit{IS}(e_1 + e_2) & = & \mathsf{mkAdd}(\mathit{IS}(e_1), \mathit{IS}(e_2)) \\ \mathit{IS}(e_1 - e_2) & = & \mathsf{mkSub}(\mathit{IS}(e_1), \mathit{IS}(e_2)) \\ \mathit{IS}(! \, e_1) & = & \mathsf{mkNot}(\mathit{IS}(e_1)) \\ \mathit{IS}(-e_1) & = & \mathsf{mkSub}(0, \mathit{IS}(e_1)) \\ & \vdots \end{array}$$

and a direct translation for the other constructs.

Memory Access

Instruction selection also introduces explicit memory access, written load and store.

A memory address is given by an expression together with a constant offset (so that we make good use of indirect addressing).

In our case, structure fields reads and assignments are turned into memory accesses.

We have a simple schema where each field is exactly one word long (since type int is assumed to be 64 bits).

So

$$IS(e_1 \rightarrow x) = load IS(e_1) (n \times wordsize)$$

 $IS(e_1 \rightarrow x = e_2) = store IS(e_1) (n \times wordsize) IS(e_2)$

where n is the index for field x in the structure and wordsize = 8 (64 bits)

With the following structure

```
struct S { int a; int b; };
```

the instruction selection for expression

$$p->a = p->b + 2$$

is

Statements and Functions

Instruction selection is a direct translation over statements (if, while, etc.).

For functions, we erase types (not needed anymore) and we gather all variables at the function level.

```
struct list {
                              // no need for type list
 int val;
                              // anymore
  struct list *next; };
int print(struct list *1) {
                              print(1) {
  struct list *p;
                                locals p, c;
 p = 1;
                                p = 1;
                                while (p) {
 while (p) {
    int c;
    c = p->val;
                                   c = load p 0;
   putchar(c);
                                  putchar(c);
    p = p->next;
                                  p = load p 8;
 return 0;
                                return 0;
                              }
```

Another Example

The classic factorial

```
int fact(int x) {
  if (x <= 1) return 1;
  return x * fact(x-1);
}</pre>
```

```
fact(x) {
  locals:
  if (setle x $1) return 1;
  return imul x fact(addi $-1 x);
}
```

The next phase transforms the code to the language RTL (Register Transfer Language).

Goal:

- get rid of the tree structure of expressions and statements, in favor of a control-flow graph (CFG), to ease further phases; in particular, we make no distinction between expressions and statements anymore
- introduce pseudo-registers to hold function parameters and intermediate computations; there are infinitely many pseudo-registers, that will later be either x86-64 registers or stack locations

Let us consider the C expression

$$b * (3 + d)$$

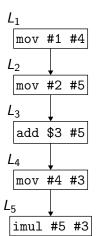

that is the syntax tree

Let us assume that b and d are in pseudo-registers #1 and #2.

And the final value in #3.

Then we build a CFG such as

CFG Representation

The CFG is a map from labels (program points) to RTL instructions.

Conversely, each RTL instruction lists the labels of the next instructions.

For instance, the RTL instruction

mov
$$n r \rightarrow L$$

means "load constant n int pseudo-register r and transfer control to label L"

optimizing compiler, part 1

```
mov n \ r \to L

load n(r_1) \ r_2 \to L

store r_1 \ n(r_2) \to L

unop op \ r \to L

binop op \ r_1 \ r_2 \to L

ubranch br \ r \to L_1, L_2

bbranch br \ r_1 \ r_2 \to L_1, L_2

call r \leftarrow f(r_1, \dots, r_n) \to L

goto \to L
```

unary operation (neg, etc.) binary operation (add, mov, etc.) unary branching (jz, etc.) binary branching (jle, etc.)

Building the CFG

We build a separate CFG for each function, with its own pseudo-registers (intraprocedural analysis).

We build the CFG from bottom to top, which means we always know the label of the continuation (the next instructions).

Translating Expressions

To translate an expression, we provide

- \bullet a pseudo-register r_d to receive its value
- ullet a label L_d corresponding to the continuation

We return the label of the entry point for the evaluation of the expression.

$$RTL(e, r_d, L_d)$$

The translation is pretty straightforward.

$$RTL(n,r_d,L_d)=$$
 add $L_1: mov \ n \ r_d
ightarrow L_d$ with L_1 fresh return L_1
$$RTL(e_1+e_2,r_d,L_d)=$$
 add $L_3: add \ r_2 \ r_d
ightarrow L_d$ with r_2,L_3 fresh
$$L_2 \leftarrow RTL(e_2,r_2,L_3)$$

$$L_1 \leftarrow RTL(e_1,r_d,L_2)$$
 return L_1

etc.

(Read the code from bottom to top).

Translating Expressions

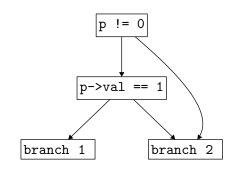

33

For local variables, we set up a table where each variable is mapped to a fresh pseudo-register.

Then reading or writing a local variable is a mov instruction (one of the RTL binary operations).

To translate C operations && and $|\cdot|$, as well as if and while statements, we use RTL branching instructions.

Example:

(the four blocks are sub-graphs)

Translating a Condition

To translate a condition, we provide two labels

- \bullet a label L_t corresponding to the continuation if the condition holds
- \bullet a label L_f when it does not hold

We return the label of the entry point for the evaluation of the condition.

$$RTL_c(e, L_t, L_f)$$

$$\begin{split} RTL_c(e_1 \&\&\, e_2, L_t, L_f) &= RTL_c(e_1,\, RTL_c(e_2, L_t, L_f),\, L_f) \\ RTL_c(e_1 \,|\, I_1, e_2, L_t, L_f) &= RTL_c(e_1,\, L_t,\, RTL_c(e_2, L_t, L_f)) \\ RTL_c(e_1 \,<= e_2, L_t, L_f) &= \operatorname{add}\, L_3 : \operatorname{bbranch}\, \operatorname{jle}\, r_2 \, r_1 \, \to L_t, L_f \\ L_2 \leftarrow RTL(e_2, r_2, L_3) \\ L_1 \leftarrow RTL(e_1, r_1, L_2) \\ \operatorname{return}\, L_1 \\ \end{split}$$

$$RTL_c(e, L_t, L_f) &= \operatorname{add}\, L_2 : \operatorname{ubranch}\, \operatorname{jz}\, r \, \to L_f, L_t \\ L_1 \leftarrow RTL(e, r, L_2) \\ \operatorname{return}\, L_1 \\ \end{split}$$

(Of course, we can handle more particular cases).

Translating Statements

To translate return, we provide a pseudo-register r_{ret} to receive the function result and a label L_{ret} corresponding to the function exit

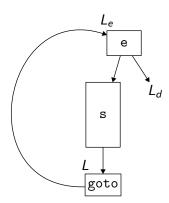

$$RTL(;, L_d) = \text{return } L_d$$

$$RTL(\text{return } e;, L_d) = RTL(e, r_{ret}, L_{ret})$$

$$RTL(\text{if}(e) s_1 \text{ else } s_2, L_d) = RTL_c(e, RTL(s_1, L_d), RTL(s_2, L_d))$$
etc.

For a while loop, we have to build a cycle in the CFG.

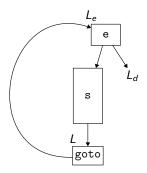

```
while (e) {
    ...s...
}
```

39

$$RTL(\text{while}(e)s, L_d) = L_e \leftarrow RTL_c(e, , RTL(s, L), L_d)$$

 $add \ L: goto \ L_e$
 $return \ L_e$

The formal parameters of a function, and its result, now are pseudo-registers

As well as actual parameters and result in a call.

Translating a Function

Translating a function involves the following steps:

- 1. we allocate fresh pseudo-registers for its parameters, its result, and its local variables
- 2. we start with an empty graph
- 3. we pick a fresh label for the function exit
- 4. we translate the function body to RTL code, and the output is the entry label in the CFG

With the factorial function

```
int fact(int x) {
  if (x <= 1) return 1;
  return x * fact(x-1);
}</pre>
```

we get

```
#2 fact(#1)
 entry: L10
 exit: I.1
 locals:
 I.10: mov #1 #6 -> I.9
 L9 : jle $1 #6 -> L8, L7
 L8 : mov $1 #2 -> L1
 L7 : mov #1 #5 -> L6
 L6: add $-1 #5 -> L5
 L5 : call #3<-fact(#5)-> L4
 L4 : mov #1 #4
                  -> L3
 L3 : mov #3 #2
                  -> L2
                  -> L1
 L2 : imul #4 #2
```

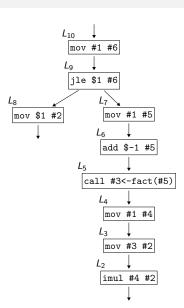

(the graph is printed arbitrarily)

43

With the factorial function

```
int fact(int x) {
  if (x <= 1) return 1;
  return x * fact(x-1);
}</pre>
```

we get

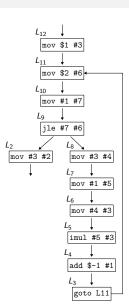

With a loop

```
int loop(int x) {
  int r;
  r = 1;
  while (2 <= x) {
    r = r * x;
    x = x - 1;
  }
  return r;
}</pre>
```

```
#2 loop(#1)
  entry: L12
  exit : L1
 locals: #3
 L12: mov $1 #3 -> L11
 L11: mov $2 #6 -> L10
 L10: mov #1 #7 -> L9
 L9 : jle #7 #6 -> L8, L2
 L8 : mov #3 #4 -> L7
 L7 : mov #1 #5 -> L6
 L6 : mov #4 #3 -> L5
 L5 : imul #5 #3 -> L4
 L4: add $-1 #1 -> L3
 L3: goto L11
  L2 : mov #3 #2 -> L1
```

With a loop

```
int loop(int x) {
  int r;
  r = 1;
  while (2 <= x) {
    r = r * x;
    x = x - 1;
  }
  return r;
}</pre>
```

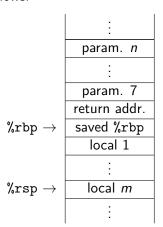

The third phase turns RTL into ERTL (Explicit Register Transfer Language).

Goal: make calling conventions explicit, namely

- the first six parameters are passed in %rdi, %rsi, %rdx, %rcx, %r8, %r9 and the next ones on the stack
- the result is returned in %rax
- in particular, putchar and malloc are library functions with a parameter in %rdi and a result in %rax
- the division idivq requires dividend and quotient in %rax
- callee-saved registers must be preserved by the callee (%rbx, %r12, %r13, %r14, %r15, %rbp)

The stack frame is as follows:

The m local variables area will hold all the pseudo-registers that could not be allocated to physical registers; register allocation (phase 4) will determine the value of m.

In ERTL, we have those same instructions as in RTL:

```
mov n r \to L

load n(r_1) r_2 \to L

store r_1 n(r_2) \to L

unop op \ r \to L

binop op \ r_1 \ r_2 \to L

ubranch br \ r \to L_1, L_2

bbranch br \ r_1 \ r_2 \to L_1, L_2

goto \to L
```

```
unary operation (neg, etc.)
binary operation (add, mov, etc.)
unary branching (jz, etc.)
binary branching (jle, etc.)
```

In RTL, we had

call
$$r \leftarrow f(r_1, \dots, r_n) \rightarrow L$$

In ERTL, we now have

call
$$f(k) \rightarrow L$$

i.e., we are only left with the name of the function to call, since new instructions will be inserted to load parameters into registers and stack, and to get the result from %rax.

We only keep the number k of parameters passed into registers (to be used in phase 4).

ERTL Instructions (3/3)

50

Finally, we have new instructions:

```
alloc_frame \to L allocate the stack frame delete_frame \to L delete the stack frame (note: we do not know its size yet)

get_param n \ r \to L access a parameter on stack (with n(\mbox{"rbp})) push_param r \to L push the value of r

return explicit return instruction
```

Inserting New Instructions

51

We do not change the structure of the control-flow graph; we simply insert new instructions

- At the beginning of each function, to
 - allocate the stack frame
 - save the callee-saved registers
 - copy the parameters into the corresponding pseudo-registers
- At the end of each function, to
 - copy the pseudo-register holding the result into %rax
 - restore the callee-saved registers
 - · delete the stack frame
 - execute return
- Around each function call, to
 - copy the pseudo-registers holding the parameters into %rdi, ... and on the stack before the call
 - copy %rax into the pseudo-register holding the result after the call
 - pop the parameters, if any

Translation

52

We translate each RTL instruction to one/several ERTL instructions.

Mostly the identity operation, except for calls and division.

Dividend and quotient are in %rax.

The RTL instruction

$$L_1$$
: binop div r_1 $r_2 \rightarrow L$

becomes three ERTL instructions

 L_1 : binop mov r_2 %rax $\rightarrow L_2$ L_2 : binop div r_1 %rax $\rightarrow L_3$

 L_3 : binop mov %rax $r_2 o L$

where L_2 and L_3 are fresh labels

Beware of the direction: here we divide r_2 by r_1 .

We translate the RTL instruction

$$L_1: call \ r \leftarrow f(r_1, \ldots, r_n) \rightarrow L$$

into a sequence of ERTL instructions

- 1. copy min(n,6) parameters r_1, r_2, \ldots into %rdi,%rsi,...
- 2. if n > 6, pass other parameters on the stack with push_param
- 3. execute call $f(\min(n,6))$
- 4. copy %rax into r
- 5. if n > 6, pop $8 \times (n-6)$ bytes

that starts at the same label L_1 and transfers the control at the end to the same label L.

The RTL code

is translated into the ERTL code

```
L5 : mov #5 %rdi -> L12
L12: call fact(1) -> L11
L11: mov %rax #3 -> L4
```

Translating Functions

RTL

ERTL

```
r f(r,..,r)
  locals : { r, ... }
  entry : L
  exit : L
  cfg : ...
f(n)
  locals : { r, ... }
  entry : L
  entry : L
  cfg : ...
```

Callee-Saved Registers

For each callee-saved register, we allocate a fresh pseudo-register to save it, that we add to the local variables of the function.

Note: for the moment, we do not try to figure out which callee-saved registers will be used by the function.

Function Entry

At the function entry, we

- allocate the stack frame with alloc_frame
- save the callee-saved registers
- copy the parameters into their pseudo-registers

```
RTL ERTL
```

```
#2 fact(#1)
                                fact(1)
  entry: L10
                                  entry: L17
 exit : L1
  locals:
                                  locals: #7, #8
                                  L17: alloc frame
                                                     -> L16
                                  L16: mov %rbx #7 -> L15
                                  L15: mov %r12 #8 -> L14
                                  L14: mov %rdi #1
                                                     -> I.10
  I.10: mov #1 #6
                                  I.10: mov #1 #6
                                                     -> I.9
                    -> L9
  . . .
                                   . . .
```

To make things simpler, we here assume that callee-saved registers are limited to %rbx and %r12 (in practice, we also have %r13, %r14, %r15).

Function Exit

At function exit, we

- copy the pseudo-register holding the result into %rax
- restore the saved registers
- delete the stack frame

61

RTL ERTL

```
#2 fact(#1)
  entry : L10
  exit : L1
  locals:
    ...
  L8 : mov $1 #2 -> L1
    ...
  L2 : imul #4 #2 -> L1
```

```
fact(1)
 entry: L17
 locals: #7, #8
                   -> L1
 L8 : mov $1 #2
 L2 : imul #4 #2 -> L1
 L1 : mov #2 %rax -> L21
 L21: mov #7 %rbx -> L20
 L20: mov #8 %r12 -> L19
 L19: delete frame -> L18
```

L18: return

62

Altogether, we get the following ERTL code:

```
fact(1)
 entry: L17
 locals: #7,#8
 L17: alloc frame -> L16
 L16: mov %rbx #7 -> L15
 L15: mov %r12 #8 -> L14
 L14: mov %rdi #1 -> L10
 L10: mov #1 #6 -> L9
 L9 : jle $1 #6 -> L8, L7
 L8 : mov $1 #2 -> L1
            -> L22
 L1: goto
 L22: mov #2 %rax -> L21
 L21: mov #7 %rbx -> L20
```

```
L20: mov #8 %r12 -> L19
L19: delete_frame -> L18
I.18: return
L7 : mov #1 #5 -> L6
L6: add $-1 #5 -> L5
               -> L13
L5 : goto
L13: mov #5 %rdi -> L12
L12: call fact(1) -> L11
L11: mov %rax #3
                 -> L4
L4 : mov #1 #4
                 -> L3
L3 : mov #3 #2 -> L2
L2 : imul #4 #2 -> L1
```

This is far from being what we think is a good x86-64 code for the factorial.

At this point, we have to understand that

 register allocation (phase 4) will try to match physical registers to pseudo-registers to minimize the use of the stack and the number of mov.

if for instance we map #8 to %r12, we remove the two instructions at L15 and L20.

• the code is not linearized yet (the graph is simply printed in some arbitrary order); this will be done in phase 5, where we will try to minimize jumps.

An Interesting Optimization

If we intend to optimize tail calls, it has to be done during the RTL to ERTL translation.

indeed, the ERTL instructions will differ, and this change influences the next phase (register allocation)

There is a difficulty, however, if the called function in a tail call does not have the same number of stack parameters or of local variables, since the stack frame has to be modified.

At least two solutions

- limit tail call optimization to cases where the stack frame has the same layout; this is the case for recursive calls!
- the caller patches the stack frame and transfers the control after the instructions that allocate the stack frame

The next phase translates ERTL to LTL (Location Transfer Language).

The goal is to get rid of pseudo-registers, replacing them with

- physical registers preferably
- stack locations otherwise

This is called register allocation.

Register allocation is complex, and decomposed into several steps

- 1. We perform a liveness analysis
 - it tells when the value contained in a pseudo-register is needed for the remaining of the computation
- 2. We build an interference graph
 - it tells what are the pseudo-registers that cannot be mapped to the same location
- 3. We allocate registers using a graph coloring
 - it maps pseudo-registers to physical registers or stack locations

In the following, a *variable* stands for a pseudo-register or a physical register.

Definition (live variable)

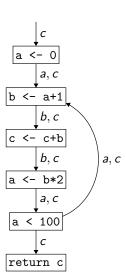

Given a program point, a variable is said to be live if the value it contains is likely to be used in the remaining of the computation.

We say "is likely" since "is used" is not decidable; so we seek for a sound over-approximation.

69

Live variables are drawn on edges

```
mov $0 a
mov $1 b
L1: mov a c
mov b a
add c b
jl $1000 b L1
mov a %rax
```

70

Live variables can be deduced from definitions and uses of variables by the various instructions.

Definition

For an instruction at label I in the control-flow graph, we write

- def(I) for the set of variables defined by this instruction,
- use(I) for the set of variables used by this instruction.

Example: for the instruction add r_1 r_2 we have

$$def(I) = \{r_2\}$$
 and $use(I) = \{r_1, r_2\}$

Computing Live Variables

71

To compute live variables, it is handy to map them to labels in the control-flow graph (instead of edges).

But then we have to distinguish between variables live at entry and variables live at exit of a given instruction.

Definition

For an instruction at label I in the control-flow graph, we write

- in(1) for the set of live variables on the set of incoming edges to 1,
- out(I) for the set of live variables on the set of outcoming edges from I.

The equations defining in(I) and out(I) are the following

$$\begin{cases} in(I) &= use(I) \cup (out(I) \setminus def(I)) \\ out(I) &= \bigcup_{s \in succ(I)} in(s) \end{cases}$$

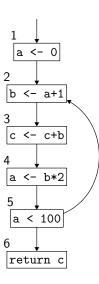

These are mutually recursive functions and we seek for the smallest solution.

We are in the case of a monotonous function over a finite domain and thus we can use Tarski's theorem (see lecture 4).

here we go again...

72

Fixpoint Computation

$$\begin{cases} in(I) = use(I) \cup (out(I) \setminus def(I)) \\ out(I) = \bigcup_{s \in succ(I)} in(s) \end{cases}$$

	use	def	in	out	in	out	in	out
1		a						а
2		b				a	 а	a,b
3	а	С	a		а	b	 a,b	b,c
4	b	a	b		b	b,c	 b,c	a,b,c
5	b,c	b	b,c		b,c	b	 a,b,c	a,b
6	b		b		b	а	 a,b	a,b
7	а		a		а		 а	

We get the fixpoint with 7 iterations.

Fixpoint Computation

74

Assuming the control-flow graph has N nodes and N variables, a brute force computation has complexity $O(N^3)$ in the worst case.

We can improve efficiency in several ways

- traversing the graph in "reverse order" and computing *out* before *in* (on the previous example, we converge in 3 iterations instead of 7)
- merging nodes with a unique predecessor and a unique successor (basic blocks)
- using a more subtle algorithm that only recomputes the in and out that may have changed; this is Kildall's algorithm

75

Idea: if in(I) changes, then we only need to redo the computation for the predecessors of I

$$\begin{cases} out(I) = \bigcup_{s \in succ(I)} in(s) \\ in(I) = use(I) \cup (out(I) \setminus def(I)) \end{cases}$$

Here is the algorithm:

```
let WS be a set containing all nodes
while WS is not empty
  remove a node l from WS
  old_in <- in(l)
  out(l) <- ...
  in(l) <- ...
  if in(l) is different from old_in(l) then
    add all predecessors of l in WS</pre>
```

Computing def and use

Computing the sets def(I) (definitions) and use(I) (uses) is straightforward for most instructions.

Examples:

	def	use
mov n r	{ <i>r</i> }	Ø
$mov r_1 r_2$	$\{r_2\}$	$\{r_1\}$
unop <i>op r</i>	{ <i>r</i> }	{ <i>r</i> }
goto	Ø	Ø

Computing def and use

This is more subtle for function calls.

For a call, we express that any caller-saved register may be erased by the call.

	def	use			
call $f(k)$	caller-saved	the first k registers of $rdi, rsi,, r9$			

Last, for return, we express that %rax and all callee-saved registers may be used.

	def	use
return	Ø	${\text{\normalfont \mathbb{N}}} \cup \textit{callee-saved}$

-> L4

-> L3

-> L2

-> L1

78

This was the ERTL code for fact

Mário Pereira

```
fact(1)
                              L20: mov #8 %r12 -> L19
